THE LAST MAXIMUM ICE EXTENT AND SUBSEQUENT DEGLACIATION OF THE PYRENEES: AN OVERVIEW OF RECENT RESEARCH

M. DELMAS

Université de Perpignan-Via Domitia, UMR 7194 CNRS, Histoire Naturelle de l’Homme Préhistorique, 52 avenue Paul Alduy 66860 Perpignan, France.

ABSTRACT. This paper reviews data currently available on the glacial fluctuations that occurred in the Pyrenees between the Würmian Maximum Ice Extent (MIE) and the beginning of the Holocene. It puts the studies published since the end of the 19th century in a historical perspective and focuses on how the methods of investigation used by successive generations of authors led them to paleogeographic and chronologic conclusions that for a time were antagonistic and later became complementary. The inventory and mapping of the ice-marginal deposits has allowed several glacial stades to be identified, and the successive ice boundaries to be outlined. Meanwhile, the weathering grade of moraines and glaciofluvial deposits has allowed Würmian glacial deposits to be distinguished from pre-Würmian ones, and has thus allowed the Würmian Maximum Ice Extent (MIE) –i.e. the starting point of the last deglaciation– to be clearly located. During the 1980s, $^{14}$C dating of glaciolacustrine sequences began to indirectly document the timing of the glacial stades responsible for the adjacent frontal or lateral moraines. Over the last decade, in situ-produced cosmogenic nuclides ($^{10}$Be and $^{36}$Cl) have been documenting the deglaciation process more directly because the data are obtained from glacial landforms or deposits such as boulders embedded in frontal or lateral moraines, or ice-polished rock surfaces. On that basis, it is now accepted that (i) the Würmian MIE occurred in the Pyrenees during MIS 4 and not the Global LGM; and that (ii) a major glacial readvance took place during the Global LGM. This ice readvance reached a position close to the MIS 4 icefield boundary in the Eastern part of the range, but apparently not in the west. (iii) Soon after the Global LGM, the Pyrenean ice margin went into major and rapid recession. Even before the beginning of the Lateglacial, the main trunk glaciers had already retreated to the upper parts of the valleys. (iv) The paleogeography of the Pyrenean icefield during the Last Glacial-Interglacial Transition (LGIT) is still partially unknown but all available data indicate that glaciers during the Oldest Dryas (GS-2a) were substantially smaller than during the Global LGM. During the Bølling-Allerød interstadial, the Pyrenean ice margins retreated substantially, and glaciers
locally vanished definitively. The Younger Dryas cooling event generated either a short readvance of existing cirque glaciers or the development of rock glaciers.

La última máxima extensión del hielo y posterior deglaciación de los Pirineos: revisión de la investigación reciente

RESUMEN. Este trabajo revisa los datos disponibles sobre las fluctuaciones glaciares que ocurrieron en los Pirineos entre la máxima extensión wurmiense del hielo y el comienzo del Holoceno. Sitúa los estudios publicados desde finales del siglo XIX en una perspectiva histórica y analiza cómo los métodos de investigación utilizados por sucesivas generaciones de autores les condujeron a conclusiones paleogeográficas y cronológicas que fueron antagonistas durante un tiempo y más tarde pasaron a ser complementarias. El inventario y cartografía de los depósitos glaciares marginales ha permitido identificar diferentes estadios glaciares y delimitar la extensión del hielo. Además, el grado de meteorización de las morrenas y de los depósitos glaciofluviales ha permitido distinguir los depósitos glaciares wurmienses de los pre-wurmienses, así como localizar claramente la máxima extensión de los glaciares wurmienses, es decir, el punto de partida de la última deglaciación. Durante los años 80 del siglo XX la dación mediante $^{14}$C de secuencias glaciolacustres documentó indirectamente el momento de los estadios glaciares responsables de las morrenas frontales o laterales adyacentes. Durante la última década, la dación mediante cosmógenicos ($^{10}$Be y $^{36}$Cl) ha documentado los procesos de deglaciación de manera más directa porque los datos se han obtenidos de formas glaciares o de depósitos, tales como grandes bloques integrados en morrenas frontales o laterales o superficies rocosas pulidas. Sobre esta base, se acepta ahora que (i) la máxima extensión del hielo wurmiense ocurrió en los Pirineos durante el MIS 4 y no durante el Último Máximo Global; y (ii) que un gran reavance glacial ocurrió durante el Último Máximo Global. Este reavance del hielo ocupó una posición próxima al límite del hielo durante el MIS 4, aunque aparentemente no en la parte más occidental. (iii) Después del Último Máximo Global los glaciares pirenaicos entraron en una gran y rápida recesión. Incluso antes del comienzo del Tardiglaciar las principales lenguas glaciares ya se habían retirado hacia las partes superiores de los valles. (iv) La paleogeografía de los campos de hielo pirenaicos durante la última transición glacial-interglacial se desconoce todavía parcialmente, aunque todos los datos disponibles indican que durante el Oldest Dryas (GS-2a) los glaciares fueron sustancialmente menores que durante el Último Máximo Global. Durante el interestadial Bølling-Allerød los glaciares pirenaicos se retiraron notablemente, y localmente desaparecieron de manera definitiva. El evento frío del Younger Dryas dio lugar a un corto reavance de los glaciares de circo o al desarrollo de glaciares rocosos.

Key words: Würmian icefield boundary, Global LGM, Last Glacial-Interglacial Termination, cosmogenic nuclides, radiocarbon dating, Pyrenees.
Palabras clave: límites del hielo wurmiense, Último Máximo Global, Último final Glacial-Interglacial, cosmogénicos, datación por radiocarbono, Pirineos.

1. Introduction

A growing body of research has been focusing on the glacial extent and chronology of Pyrenean Pleistocene glaciations. The modalities of the last deglaciation, however, are still poorly known, likely because studies published until now have mainly dealt with terminal moraine systems and much less with till deposits located farther up-valley and in the cirques. This paper reviews current knowledge of glacial fluctuations in the Pyrenees between the last Maximum Ice Extent (MIE) and the beginning of the Holocene. It also provides a synthesis of the glacial extent and chronology of the Würmian MIE because these data set the starting point of the last deglaciation process. The Global LGM is defined as the time of the most recent and largest globally integrated ice mass. This latest peak volume of ice on Earth prevailed between 23 ka cal. BP and 19 ka cal. BP (MARGO project Members, 2009) and coincided with extremely low and stable sea levels (-135 m). The Last Glacial-Interglacial Transition (LGIT) refers to the time interval between the Global LGM and the beginning of the Holocene (Wohlfarth, 1996; Hoek, 2009; Denton et al., 2010). This time interval was characterized by intense, fast and abrupt climatic changes. The LGIT-related climatic changes were initially detected from North European pollen records (Oldest Dryas-, Bølling-, Older Dryas-, Allerød-, Younger Dryas- and Preboreal-Chronozones, Mangerud et al., 1974), but has now been well constrained and well dated with the help of isotopic data from the Greenland ice cores, proposing a new terminology and chronology that is widely accepted (Rasmussen et al., 2006; Lowe et al., 2008; Svensson et al., 2008; Blockley et al., 2012; Rasmussen et al., 2014).

In the Pyrenees, the time range likely to cover the deglaciation process is a priori longer than that recorded on a global scale (i.e., during the strict duration of the LGIT) because all the geochronological data acquired from Pyrenean terminal moraines indicate that the last Pyrenean MIE occurred earlier than the Global LGM and was, instead, contemporaneous of the MIS 4 (review in Calvet et al., 2011; García-Ruiz et al., 2013).

What happened in the Pyrenees between MIS 4 and the beginning of the Holocene? When did the outlet glaciers retreat back from the Würmian MIE terminal moraines and become confined to the valley headwaters? Was it during MIS 3, or only after the Global LGM? Where were Pyrenean glaciers positioned during the Global LGM? Were they far apart, or, instead, quite close to the MIS 4 one another? What was finally the impact of the climatic changes that occurred during the LGIT on the Pyrenean ice extent? Here
we try to answer these questions through a historiographic presentation of research on Pyrenean glaciation since the end of the 19th century.

2. The Würmian MIE, starting point of the last deglaciation: a century of research

The paleogeography and chronology of the Würmian MIE, or maximum icefield boundary, are now well established (Fig. 1; Calvet et al., 2011). These limits are based on one century of mapping of ice-margin deposits. We outline here how the chronological and spatial setting of the Würmian MIE has determined how researchers have conceptualized the process of deglaciation.

2.1. The first maps and the dispute between monoglacialists and polyglacialists

A. Penck published extremely detailed reviews of the glacial landscapes and deposits of the Pyrenees in 1883 and 1894, i.e. 25 years before the publication of the famous synthesis on Alpine glaciations by Penck and Brückner (1909-1910). These early Pyrenean reviews did not address issues of chronology. During the 20th century, the inventory and mapping of ice-margin deposits continued on the north (Mengaud, 1910; Depéret, 1927; Faucher, 1937; Goron, 1941) as well as the south sides of the mountain range (Panzer, 1926; Llopis-Lladó, 1947; Fontboté, 1948). These studies identified three sedimentary units associated with three contrasting ice extents (Viers, 1961; Taillefer, 1963; Barrère, 1963). The “moraines externes”, or outermost moraines, locate the maximum extent of the Pleistocene glaciers, whereas the “moraines internes” (or “stades de disjonction”) refer to a time after which tributary glaciers became disconnected from the trunk glacier and began to produce their own frontal moraines in the tributary valleys. Finally, the “moraines des cirques” describe the third and final period when the
ice was confined to the floors of glacial cirques. A similar terminology remained in use on the south side of the range until the early 1990s (Fig. 2).

**Figure 2. Relative chronostratigraphy of Pyrenean glacial deposits. After Bordonau, 1992, modified.**

The issue of allocating ages to the glacial deposits increasingly became a concern, and until the 1980s features such as the state of clast weathering, soil types, and deposit position in the landscape remained the main relative dating criteria. Until the late 1960s, analogies with the Alpine model (or, conversely, reactions against this model) fueled the debate. As a result, the 1950s and 1960s were a time of sharp debates between polyglacialists and monoglacialists.

Among the polyglacialist camp, H. Alimen (1964) claimed to recognize in the valley trains of the North Pyrenean foothills (Gave d’Ossau, Gave de Pau, Adour and Neste d’Aure) the four glaciations that had been identified in the Bavarian foothills of the Alps at the beginning of the century by Penck and Brückner (1909-1910) –including the Donau glaciation later defined in its type area of the Danube valley (Eberl, 1930). The two higher terraces of the north-Pyrenean foothills were respectively correlated with the Donau and the Günz because they contained an abundance of quartzite clasts and could thus be assimilated to the Alpine Deckenschotter. The third terrace is deeply entrenched below the Günz deposits. The state of clast weathering is less intense than in the case of the previous two levels, but
the terrace deposit is nonetheless also capped by red soils. These criteria persuaded Alimen (1964) to correlate this third terrace level with the Mindel glaciation because, in the Alps, the Mindel likewise corresponded to the lower known terrace capped by red soils. Finally, again by analogy with the Alpine model, the lower level of north-Pyrenean fluvial sequences is ascribed to the Riss. Furthermore, given that the lower North-Pyrenean terraces are topographically connected to the “moraines internes”, Alimen (1964) correlated them with the Riss glaciation, and thus ascribed the “moraines internes” to the Würmian glaciation. Finally, according to Alimen (1964), the Würmian MIE corresponded to relatively small glaciers whose frontal position was located in the elevated parts of the U-shaped valleys, whereas deposits of the last deglaciation were confined to the floors of the cirques and to the crest area.

Among the monoglacialists, the inner and outer moraines were considered as the result of a single glaciation, because the weathering facies of these two units were too similar to be of different ages (Viers, 1960; Taillefer, 1960; Taillefer, 1961; Barrère, 1963). Moreover, the high and middle terraces of the North-Pyrenean foothills could not be of glaciofluvial origin because neither of those levels grades topographically with the outermost moraines of the glacial sequence (Taillefer, 1951; Viers 1963). These observations and interpretations, spearheaded by G. Viers, produced a model for understanding the Quaternary period that stood in complete contradiction with the works on global paleoclimates published during the 1950s (Emiliani, 1954). According to this model, the Pyrenees experienced only one single glaciation, which occurred at the end of the Pleistocene after a period of fluvial denudation during the Villafranchian and alluvial fan construction and forming the high and middle terraces of the North Pyrenean foothills. Thus, for the monoglacialists, the outermost moraines were a legacy of a “phase d’expansion maximale”, while moraines in more internal valley positions were the legacy of a deglacial stage named “stade de disjunction”. Lastly, moraines located in the cirques were at first ascribed to the Lateglacial (Viers, 1961, 1963, 1968) and subsequently to a “Neoglacial” period, “si proche des crêtes que la progression dont il résulte a nécessairement été précédée d’une déglaciation presque complète” (Taillefer, 1969, p. 27; Taillefer, 1967).

2.2. Recent rehabilitation of polyglacialist views and repositioning of the Würmian MIE

It was not until the beginning of the 1990s, and the first attempts at U–Th-dating the stalagmitic floors of the Niaux-Sabart-Lombrives caves (Sorriaux, 1981, 1982; Bakalowicz et al., 1984), that the multiplicity of successive Pleistocene glaciations was unanimously acknowledged (Taillefer, 1985). A growing number of radiometric ages have been published since (review in Calvet et al., 2011), although none currently span the entire Pleistocene record. This explains why the chronostratigraphy of Pleistocene deposits currently recognized in the Pyrenees is mainly based on relative criteria developed in the 1970s, which relied on the state of weathering and the soil geography of glaciofluvial terrace systems in the North-Pyrenean foothills (Icole, 1973; Hubschman, 1973, 1975a, 1975b, 1975c). These studies reflect a continuity with
the those conducted a few years earlier in the same area (Alimen, 1964) but they are based on much more advanced analytical datasets because they focus on the finer-textured fraction as well as the coarse fraction and relied on methods inspired by existing research on soil chronosequences (Birkeland, 1968, 1999). These weathering-based approaches allowed the terraces initially ascribed to the Riss and the Mindel to be reassigned instead to the Würm and the Riss, respectively. It has been established on that basis that the Würmian glaciofluvial deposits could be distinguished from their very limited state of weathering, from the sand- and gravel-rich matrix, and from the presence of eluviated brown soils; Rissian deposits (MIS 6), in contrast, were characterized by weathering profiles at least 4 to 5 m deep, exhibiting a brown to ochre matrix, weakly enriched in clay and free iron, and displaying a coarse fraction consisting of at least 50% of weathered crystalline pebbles.

This relative chronology of North-Pyrenean glaciofluvial terraces was subsequently and successfully transposed to the outer moraine systems (Hubschman, 1984; Hétu and Gangloff, 1984; Calvet, 1994, 1998). These studies, initially conducted on rivers such as the Gave d’Ossau, Gave de Pau, Garonne and Ariège, show that the boundary between the Rissian and Würmian glaciations does not run between the outer and inner moraines, as initially envisioned by the earlier polyglacialists (Alimen, 1964), but lies within the outer moraine systems. Hubschman (1984), for example, showed that the terminal moraines of the foothill zone contained two generations of till displaying significantly different states of weathering. The “moraines récentes” could be tied to the Würmian glaciation because they show a very limited state of weathering. The majority of the pebbles are unweathered. The matrix consists of coarse sand, is rich in feldspar and mica, and poor in vermiculite. These younger glacial landforms form very well preserved frontal and lateral moraines. They are conspicuous in the landscape and are connect topographically with the lower Würmian terraces of the North-Pyrenean foothill zone. In contrast, the older “moraines anciennes” are characterized by a finer, brown and ochre-colored matrix, poor in plagioclase but rich in vermiculite and showing some advanced weathering features among micaceous minerals. In many valleys on the north side of the range, these weathered moraines remain only as residual patches located relatively close to, but topographically higher than, the “moraines récentes”. Likewise, the topographic continuity with the terraces of the foothill zone is not always apparent. Where they exist, however, field evidence shows that the “moraines anciennes” are topographically connected to the middle terraces of the North Pyrenean foothills, i.e. with levels ascribed to the Rissian glacial stage (MIS 6). Based on the seminal contributions of Hubschman (1984), at least two generations of pre-Würmian tills have been identified on the Pyrenan moraines in an outer position (Hétu and Gangloff, 1984; Calvet, 1994, 1998).

In summary, by separating the deposits that are coeval with the last glacial cycle from those that are contemporaneous of previous glaciations on the basis of objective analytical criteria, these studies allowed to the Würmian MIE to be located in several Pyrenean valleys (Fig. 1). However, because there is no obvious weathering gradient between the “moraines récentes” in an outer position and the “moraines internes”
of the more interior parts of the valleys, these criteria have not allowed a relative chronostratigraphy of the Würmian deposits to be established. Gaining deeper insight into the absolute chronology of glaciation needed more radiometric dating. The first radiocarbon ages from glaciolacustrine deposits provided further insight into the chronological patterns of the last Pyrenean glaciation.

3. Contributions from radiocarbon dating

Starting in the 1980s, work on the chronology of the last glacial cycle produced an increasing number of radiocarbon ages. Most of these came from pollen cores acquired primarily for reconstructing the vegetation history since the end of the last Pleniglacial (review in Jalut et al., 1992). Sedimentological analyses were also performed on all the radiocarbon-dated sequences. These data allowed knowledge about the timing of the Würmian MIE and of the following deglaciation to be refined (review in Andrieu et al., 1988). These studies led to a chronological model significantly that was more precise than that supplied by previous relative dating attempts. However, it is important to note that this model indexed on radiocarbon dating was only based on indirect data, i.e. glaciolacustrine clays from cores situated adjacent to Würmian MIE moraines such as at Biscaye, Lourdes, Le Monge, Barbazan, Llestui, and Els Bassots. This is not identical to dating frontal or lateral moraines directly. In all of these settings, the $^{14}$C data obtained from the base of the core samples pre-date the Würmian MIE and post-date the onset of deglaciation. The close proximity between the position of the snout of the glacier and the paleolake containing the fill sequence could generally be ascertained by the presence of dropstones in the dated glaciolacustrine clays. However, when dropstones are absent, correlating ice-margin positions with the radiocarbon ages obtained from the glaciolacustrine clay becomes much less robust because proglacial streams, which tend to feed the glaciolacustrine deposits, are capable of transporting suspended load over long distances before ponding forces the particles to settle in the lacustrine sediment trap.

3.1. A chronology for the north side of the range

The first age bracket for the Würmian MIE was obtained from the proglacial fill sequence of Biscaye, where the basal glaciolacustrine unit, which contains dropstones, yielded an age of 38.4 ± 2.0 ka BP (Mardones and Jalut, 1983). A quantification of the sedimentation rate between the two older $^{14}$C ages set the age of the fill-sequence base, by extrapolation, to ~45 ka. Because this fill sequence is located just behind the Würmian MIE frontal moraine on the Gave de Pau, the authors propose to place moraine construction between 50 and 70 ka BP. Using IntCal13 (Reimer et al., 2013), the calibrated $^{14}$C age converts to between 39,541 and 47,932 ka cal. BP. Comparable results have been obtained on the Gave d’Ossau, where the Estarrès fill sequence provided an age of 27.15 ± 1.0 ka BP (29,467 to 33,761 ka cal. BP) in the glaciolacustrine rythmites at the base of the borehole (Andrieu, 1987; Jalut et al., 1988; Andrieu et al., 1988); and likewise in the Garonne valley, where the Barbazan fill sequence yielded an age of 31.16 ± 1.7 ka.
BP (32,037 to 39,407 ka cal. BP) in the glaciolacustrine rythmites and diamicton at the base of the core (Andrieu, 1991; Andrieu et al., 1988; Jalut et al., 1992). In the Ariège catchment, a $^{14}$C age from the base of the Freychinède borehole has indicated that the Würmian MIE occurred prior to 21.3 ± 0.76 ka BP, i.e. 24,056 to 27,346 ka cal. BP (Fig. 3, Jalut et al., 1982).

Following this early occurrence of the Würmian MIE, glaciers stagnated for a time in the foothill zone before receding definitively to the higher reaches of the valleys. On the Gave de Pau, although the proglacial fill sequence interrupts at 31.9 ± 2.0 ka BP (Biscaye, 32,657 to 42,182 ka cal. BP), the authors consider that the ice left the foothills only around 29.5 ± 1.2 ka (32,246 to 36,406 ka cal. BP), i.e. at a time when the Biscaye sequence and the neighboring sequences of Lourdes and Le Monge recorded an interruption of proglacial sedimentation. On the Ossau valley, the Estarrès sequence places the deglaciation of the foothill zone between 24.4 ± 1.0 ka BP (27,068 to 30,974 ka cal. BP) and 18.97 ± 1.0 ka BP (20,809 to 25,632 ka cal. BP). Data obtained in the Castet fill sequence are similar (Andrieu, 1987; Jalut et al., 1988; Andrieu et al., 1988). On the Garonne valley, the Barbazon sequence places the same event just after 26.6 ± 0.46 ka BP (29,786 to 31,446 ka cal. BP, Andrieu, 1991; Andrieu et al., 1988; Jalut et al., 1992). Because they are located in the foothills (Biscaye, Estarrès) or in their immediate vicinity (Castet), the information contained in these boreholes is restricted to the earliest stages of the deglaciation. Only two sites (Bious, Gave d’Ossau, 1550 m; Freychinède, Ariège, 1350 m) constrain the later stages of deglaciation. The data converge on the idea of a relatively early deglaciation of the upper part of the valleys. Ages of 15.8 ± 0.24 ka BP (18,641 to 19,719 ka cal. BP) from the base of the Bious fill sequence indicate that the ice had retreated to the cirques located around the Pic du Midi d’Ossau before the beginning of the Oldest Dryas (Fig. 4). This young age, however, remains doubtful given the authors’ remarks about the three other ages from farther up in the stratigraphic sequence (Jalut et al., 1988). The Freychinède sequence indicates (i) that the transfluence pass located near the fill sequence, at 1517 m, was free of ice as early as 21.3 ± 0.76 ka BP (24,056 to 27,346 ka cal. BP); and (ii) that the cirques located on the south side of the Trois Seigneurs massif supplied, at that time, a valley glacier occupying the Suc River valley, a tributary of the Vézéres valley. The terminal ice margin of this tributary glacier cannot currently be located. Nothing indicates whether or not it joined up with the trunk glacier situated in the Vézéres valley. Nonetheless, the presence of sillimanite in the glaciolacustrine sediments, from the bottom of the borehole to a depth of 396-398 cm, show that the Suc valley glacier was sufficiently thick to feed the Freychinède paleolake with juxtaglacial meltwater from metamorphic outcrops in the massif des Trois Seigneurs. (iii) After 13.15 ± 0.3 ka BP (14,859 to 16,796 ka cal. BP, dating obtained at a depth of 401-403 cm), the interruption of sillimanite-rich detrital inputs indicates that the Suc glacier no longer extended beyond the bedrock step located at 1360-1380 m a.s.l. between the Suc valley and the Freychinède fill sequence. The authors consider that, from that time, the ice was confined to the floor of the cirques located on the south side of the Trois Seigneurs massif (Fig. 3, Jalut et al., 1982).
Figure 3. Pleistocene ice extent in the Ariège catchment. 3.2. A coherent chronology for the south side of the range

The $^{14}$C ages obtained in the glaciolacustrine fill sequences of the south side of the range, particularly those in the Noguera Rigorçana valley (Fig. 5), have previously confirmed the chronological model elaborated for the north side. New data inconsistent with the initial results have, however, rekindled the debate started by Turner and Hannon (1988) over whether or not the Pyrenean Würmian MIE and the global isotopic record were truly synchronous (review in Pallàs et al., 2006). In 1983, the base of the Llestui fill sequence was dated and produced an age of ca. 33 ka$^{14}$C BP (Vilaplana, 1983a; Vilaplana and Bordonau, 1989). Later, Bordonau (1992) dated the base of the Els Bassots proglacial fill sequence and produced an age of 31.41 ± 1.2 ka BP (33,542 to 38,941 ka cal. BP). However, the author highlighted inconsistencies among the $^{14}$C ages from the fill base and doubted any synchronicity with the chronological model developed on the north side of the range. The following year, noting a number of further inconsistencies in the $^{14}$C data obtained in the Llestui fill sequence (Vilaplana, 1983a; Vilaplana and Bordonau, 1989), Bordonau et al. (1993) undertook to redate the samples. In order to take into account the presence of mineral graphite in the catchment (“old carbon” effect), the authors developed a protocol for sample preparation with the purpose of separating the organic carbon from the mineral carbon. At the end of this treatment, the results turned out to be clearly younger, and the “phase de stabilisation post-maximum” was restored to an age lying between 18.24 ± 0.6 (20,684 to 23,600 ka cal. BP) and 21.65 ± 0.9 ka BP (24,113 to 27,831 ka cal. BP). Following this revision of radiocarbon ages on the south side of the range, new boreholes were also drilled in the Biscaye, Lourdes and Le Monge fill sequences of the north side (Reille and Andrieu, 1995). However, only the Lourdes 1 borehole yielded $^{14}$C ages relevant to this study. Indeed, the age obtained in the blue glaciolacustrine clays at the base of the borehole provided an age of 20,025 ± 0.175 ka BP (23,700 to 24,557 ka cal. BP), suggesting that the Würmian MIE could be much younger than previously considered on the basis of Biscaye datings. However, the age obtained from the base of the overlying gyttja also showed that glaciolacustrine sedimentation ended before 15.46 ± 0.15 ka BP (18,436 to 19,076 ka cal. BP) and that the glacier was, by that time, confined to the higher part of the valley.

The $^{14}$C ages obtained from the glaciolacustrine fill sequence of the Gállego valley (Paul de Bubal, Ibon de Tramacastilla, Nord Tramacastilla, Fig. 4) are highly consistent with the data obtained on the north side of the range. The paper by García-Ruiz et al. (2003) was accordingly entitled “Asynchronicity of maximum glacier advances in the central Spanish Pyrenees” in reference to other European mountains. The reasoning is based on sedimentary sequences from paleolakes linked to various deglacial stades. Several ages obtained from the base of the boreholes led the authors to consider the Gállego Würmian MIE to be older than the Global LGM, even older than MIS 2. Note that the age at 29.4 ± 0.6 ka BP (32,030 to 34,736 ka cal. BP) obtained in the glaciolacustrine unit at the base of the Ibon de Tramacastilla sequence was considered unreliable by the authors, who considered the likelihood of the “hard water” and/or “old carbon” effects. A new borehole from the same ice-marginal paleolake (North Tramacastilla borehole: depth 4 m, against 14 m for Ibon de Tramacastilla borehole) yielded an AMS $^{14}$C age in proglacial silt, 275 cm from the surface, of 20.6 ± 0.17 ka BP (i.e. 24,389 to 25,345 ka cal. BP). The authors considered the latter age
to be more reliable than another of 29.4 ± 0.6 ka BP because it was obtained from a pollen assemblage rich in terrestrial taxa. According to those authors, this precaution minimizes the “hard water” effect (which artificially increases radiocarbon ages). However, it is important to emphasize that this new age can nonetheless not be directly compared to the initial result because the two samples were collected from different boreholes and thus do not date exactly the same sedimentary unit.

Figure 4. Glacial and glaciofluvial deposits, with associated exposure ages in the Gállego catchment. 1- Frontal and lateral moraines. 2A-Successive Würmian ice-margin positions. B- Middle Pleistocene (MIS 6) ice-margin position. 3- Scoured rock surfaces on bedrock steps. 4A- Location of ¹⁴C sample ages, B- OSL sample ages, C- ³⁶Cl sample ages. 5- Würmian ice-contact sedimentary units (lacustrine or fluvial). 6- Proglacial alluvial trains, poorly weathered (Qt6-7-8). 7- Proglacial alluvial trains and mantled wash pediments, weathered and rubefied (Qt5). 8- Highest alluvial deposits. 9- High-relief landforms. 10- Lakes and drainage network.

Dated OSL sites (66 ± 4 ka: Hostal de Ipies; 74 ± 10 ka: Llano de Yeste) are located 1 and 5 km from the town of Sabiñanigo, respectively (i.e. beyond the southern limit of the figure). After Palacios et al. (2015b) and Calvet et al. (2011).
Although the Gállego sites were selected and sampled mainly in order to discuss the age of the Würmian MIE, their location in the upper part of the glacial catchment makes them also interesting in terms of timing of the last deglaciation. Indeed, (i) the $^{14}$C ages of the glaciolacustrine unit of the Paul de Bubal sequence (Jalut et al., 1992) show that the Gállego glacier was located at least 15 km upstream the Senegüé frontal moraine before 20.8 ± 0.4 ka BP (24,182 to 25,928 ka cal. BP). (ii) The $^{14}$C ages obtained from the Tramacastilla boreholes (Ibon de Tramacastilla and Nord Tramacastilla) record the end of the transfluence between the Lana Major and the Escarra iceways, and also the probable disconnection between these two joined-up catchments and the main Gállego outlet glacier. Finally, (iii) the Portalet peatbog, which is located in a tributary of the Gállego within the cirque area between 2100 and 2300 m, benefited from the multi-proxy study of a 6.64 m core (González-Sampéřiz et al., 2006). The sedimentary sequence shows a stratigraphic hiatus marked by an erosional surface, a sharp break in the pollen spectra, and a very low rate of sedimentation. This stratigraphic hiatus overlies a glaciolacustrine deposit AMS-dated between 28.3 ± 0.37 ka BP (31,426 to 33,316 ka cal. BP) and 24.17 ± 0.24 ka AMS BP (27,825 to 28,743 ka cal. BP). It is followed by a continuous sedimentary sequence characterized by alternating silt levels varyingly enriched in carbonates and organic matter, and topped by 2 m of peat. The sedimentary sequence provides a continuous record of the vegetation history from 19.25 ± 0.12 ka AMS BP (22,922 to 23,588 ka cal. BP) until the middle of the Holocene (5 ka). It also indirectly documents the timing of the glacial fluctuations around the site. The basal unit, which is AMS-dated between 28.3 ± 0.37 and 24.17 ± 0.24 ka BP, is coeval with an interstadial during which the upper valley around the peatbog was occupied by small glaciers confined to the cirque floors situated in the catchment above the paleolake. Between 24.17 ± 0.24 and 19.25 ± 0.12 ka AMS BP, the authors reconstructed two successive events. (i) The stratigraphic hiatus is associated with a glacial advance ascribed to the Global LGM. After 24.17 ± 0.24 AMS BP, the glaciers were confined to the cirque floors but advanced into the valley and overrode the paleolake. However, there is no evidence that this glacial advance reached the Gállego trunk glacier. (ii) The sedimentary sequence that overlies the stratigraphic unconformity shows that, ca. 19.25 ± 0.12 ka AMS BP (22,922 to 23,588 ka cal. BP), the area around the Portalet peatbog was once again ice-free. However, given the lack of proglacial sedimentation in the post-erosional fill sequence, this time the ice had probably receded as far back as the iceshed. The authors note that all $^{14}$C AMS ages were obtained from pollen assemblages rich in terrestrial taxa in order to minimize the risk posed by the “hard water” effect. To summarize, the data obtained throughout the Gállego glacial catchment are internally consistent, especially taking into account that the Tramacastilla and Portalet paleolakes are located in tributaries of the Gállego valley less well supplied than ice flow from the Sallent and Panticosa massifs –where the higher summits reach 3000 m and may have fed a large glacier at a time when the Tramacastilla and Portalet sites were already ice-free.

Farther east, sequence stratigraphy and $^{14}$C AMS ages from La Massana paleolake in Andorra (Turu i Michels, 2002) allow the timing of the first steps of the last deglaciation in the Andorran valleys to be reconstructed (Fig. 3). During the Würmian MIE, Andorra was covered by a large composite outlet glacier fed by the
confluence of the Valira d’Orient (Gran Valira) and the Valira del Nord tributaries—the latter being itself fed from the confluence between the local valley glaciers of Arinsal and Ordino. La Massana paleolake is thus contemporaneous of a deglacial stade during which the Arinsal and Ordino were confined to their upper valleys, while the Valira d’Orient was still large enough to obstruct the Valira del Nord. The sequence stratigraphy of the paleolake fill sequence has allowed changes in paleolake water levels, and thus changes in the Gran Valira ice thickness, to be inferred. It has also provided a record of climate-driven fluctuations of the local Arinsal and Ordino glaciers, which overrode the paleolake deposits at regular intervals. Numbers of $^{14}$C AMS ages obtained in this fill sequence place the disconnection of the two Valira valley glaciers and ponding of the paleolake before 25.64 ± 0.19 ka BP (19,352 to 30,482 ka cal. BP). One $^{14}$C age on organic colluvium drilled in the giant landslide of El Forn (Canillo) indicates that the disconnection between the two Valira occurred before 34.25 ± 0.32 ka BP (i.e. 38,151 to 39,667 ka cal. BP, Planas et al., 2011). At this time, the ice terminal position of the Valira d’Orient was located 25 km upstream of the MIE terminal position. Thereafter, the Massana record shows a relative persistence of the paleolake until about 15.49 ± 0.07 ka AMS BP (18,617 to 18,909 ka cal. BP). This shows that the Global LGM glacial advance, which is recorded by a prograding till in the sedimentary sequence, did not reach the position of the Würmian MIE. A glacial advance was also recorded during the Oldest Dryas, but after 15.49 ± 0.07 ka AMS BP (18,617 to 18,909 ka cal. BP) the definitive interruption of glaciolacustrine sedimentation in the Massana basin indicates that the Valira d’Orient glacier was, by that time, confined to the higher part of the valley.

Two other high-elevation sites confirm an early deglaciation of the Pyrenees compared to other north-European mountains. In the Noguera de Tor valley, the glaciers were confined to the cirques located upstream from Estany Redó d’Aigues Tortes (2110 m d’altitude, Fig. 5) from the Oldest Dryas onward, as shown by an AMS age of 13.47 ± 0.06 ka BP (16,045 to 16,500 ka cal. BP) in the basal glaciolacustrine unit of the borehole (Copons and Bordonau, 1996). Even more telling data were acquired in the Eastern Pyrenees, at the Grave site (2150 m) in the upper part of the Têt valley just below the cirque zone, where a buried peatbog yielded three $^{14}$C highly consistent ages (Fig. 6). These data indicate that glaciation was confined to the cirques as early as 19-20 ka cal. BP, i.e. before the beginning of the LGIT (Delmas, 2005; Delmas et al., 2008). The authors ascribed this major event to one of the multiple temperate oscillations that characterize the GS-2b stadial of the INTIMATE stratigraphy (Svensson et al., 2008).

4. Contributions from cosmogenic nuclides and OSL dating

In the 21st century, dating methods became more diversified. OSL data from the moraine and glaciofluvial systems of the Cinca and the Gállego (Sancho et al., 2003, 2004; Peña et al., 2004; Lewis et al., 2009), the Valira (Turu i Michels and Peña Moné, 2006) and the Aragon valleys (García-Ruiz et al., 2013) were published. At the same
The last maximum ice extent and subsequent deglaciation of the Pyrenees

4.1. OSL data confirm the antiquity of the Würmian MIE (MIS 4)

OSL data acquired on the south side of the range have been obtained from the sequence of glaciofluvial terraces located in the foothill zone. The high and middle terraces have been ascribed to MIS 6, and even to MIS 8 in the Aragon valley. On the poorly weathered Würmian glaciofluvial levels of the Cinca, Gállego and Aragon valleys, OSL dating has focused on glaciofluvial terraces as well as terminal moraines. In the Cinca valley, the Salinas till and its connected Qt7 terrace indicate a weighted average age of 64 ± 11 ka (3 OSL ages) and of 61 ± 4 ka (6 OSL ages), respectively. In the Gállego valley, the Aurín moraine, which was formed during the Würmian MIE, is dated at 85 ± 5 ka (another OSL age of 38 ± 4 ka was discarded by the authors), but the Sabiñanigo terrace (Qt7), which is situated in the downstream continuation of the Aurín till, yielded a weighted average age of 68 ± 7 ka (based on 3 OSL results: 69 ± 8 ka at Sabiñanigo, 66 ± 4 ka at Hostal de Ipies, and 74 ± 10 ka at Llano de Yeste). The frontal moraine of Senegüe, which is located 2 km upstream from the Aurín moraines, has been dated to 36 ± 3 ka (two OSL ages by Lewis et al., 2009, Fig. 4). Finally, data acquired from the Aragon valley are relatively similar to those acquired in the Cinca valley given that the moraine corresponding to the Würmian MIE yielded an age of 67 ± 8 ka (single OSL age by García-Ruiz et al., 2013).

4.2 Cosmogenic ages cover the entire Würmian glacial sequences

Whereas OSL data only concern the moraines of outlet glaciers in outer foothill positions, cosmogenic dating in the Pyrenees has begun to cover the entire Würmian sequences from the Würmian MIE moraines to the moraines of the cirque headwaters. All the data acquired in the Pyrenees by this method come either from samples of glacially polished bedrock surfaces or from exposed boulders on moraine crests. Ages obtained on glacially scoured bedrock surfaces document the time when retreating ice exposed the bedrock step for the first time. Ages obtained on moraine boulders indicate the time of moraine abandonment and stabilization due to glacier retreat (Zreda and Phillips, 1994, 1995; Putkonen and O’Neal, 2006; Putkonen et al., 2008). In all cases, the cosmogenic data provide minimum exposure ages because...
the method postulates that sampled surfaces have undergone no erosion since their initial exposure. This assumption is acceptable when supported by suitable field evidence, hence the value of sampling large boulders situated on high and well-preserved moraines.

4.2.1. Confirmation for the antiquity of the Würmian MIE, and first evidence of the terminal position of Pyrenean outlet glaciers during the Global LGM

The first ages for the Würmian MIE obtained in the Noguera Ribagorçana and Têt river valleys (Pallàs et al., 2006, Delmas et al., 2008) do not come from the outermost Würmian moraines but from moraines located a few hundred meters up-valley (Fig. 7). Ages of 21-22 ka obtained on these moraines were briefly poised to re-open the debate on the possibility of a time lag between the Pyrenean Würmian MIE and the Global LGM. This time, however, the debate was short-lived because, as soon as 2010 and 2011, new cosmogenic ages from the Querol, Malniu, and Ariège river valleys showed that, at least in the eastern Pyrenees, MIS 4 terminal moraines stood very closed to those attributable to the Global LGM (Pallàs et al., 2010; Delmas et al., 2011). On that basis, Delmas et al. (2011) considered that the Pyrenean outlet glaciers during MIS 4 and during the Global LGM reached almost similar positions in Pyrenean massifs under Mediterranean climatic influence. Meanwhile, in the western part of the range, i.e. in massifs under Atlantic influence, glaciers during the Global LGM were substantially shorter than during MIS 4. It is thus conceivable that, during the Global LGM at this latitude, cyclogenesis in the Western Mediterranean was more intense and more effective at producing snowfall than North Atlantic weather systems. Concurring evidence has been independently suggested by the sea-surface temperatures recorded for the Global LGM in the Balearic waters (with 9-10°C winter and 14-16°C summer averages) and the Bay of Biscay (2.1 to 3.2°C in winter, 11.8 to 13.3°C in summer, Hayes et al., 2005; de Vernal et al., 2005, 2006). This nonetheless remains a partial assumption because the real terminal position of the Pyrenean glaciers during the Global LGM is still not fully constrained in a number of valleys of the western Pyrenees –for example all the valleys located west of the Ariège. Radiocarbon ages acquired in the 1980s and the 1990s indicate an early deglaciation of the foothill zone, even before the Global LGM (see section 2.1). These, however, are indirect data and should be clarified. Cosmogenic ages have been produced on the outer moraines of the Gave de Pau, precisely for this purpose (Rodes, 2008). Results were not up to expectation because Holocene climatic conditions in the North-Pyrenean foothills exhibit quite intensely weathered rock surfaces, particularly on boulders. Given that post-glacial erosion rates since initial exposure remain unknown, the true exposure ages of the boulders located on the Würmian MIE terminal moraine of the Gave de Pau have not been definitively established. On the south side of the range, the position of the Global LGM terminal moraines has been identified in the easternmost massifs of the range (southeastern side of the Carlit massif, Querol, Malniu, Duran, Llosa, and Arànser: Delmas et al., 2008; Pallàs et al., 2010; Palacios et al., 2015a, Fig. 7) and on the Noguera Ribagorçana (Pallàs et al., 2006, Fig. 5). There is no direct evidence yet from valleys situated farther to the west.
4.2.2. Instability of Würmian ice-margin positions: preliminary evidence

Evidence of inherited nuclides on polished bedrock steps has revealed the existence of large fluctuations (10 km at least) of the Ariège glacier during MIS 3. Because these occurrences of inheritance are located upstream of the Global LGM frontal moraines, they indicate that the Ariège glacier was affected during MIS 3 by one or several recessional episodes that shortened the outlet glacier by at least 10 km from the Würmian MIE terminal position. This shows that the post-MIS 4 history of Pyrenean glaciation is more complex than previously detected by $^{14}C$ dating. Radiocarbon ages obtained from glaciolacustrine fill sequences have tended to convey a spurious understanding of the last glacial cycle as a simple event involving a single glacial advance, which reached a single maximum ice extent, followed by a single phase of deglaciation, interspersed with
brief episodes of stagnation or short-range advances during which a suite of frontal and lateral moraines were constructed. All ages directly acquired on ice-margin deposits implicitly lead to the same kind of deglacial model. For example, on the Gállego River, the Senegüe moraine, which has been correlated with MIS 3, could be interpreted as the first deglaciation stade that followed the Würmian MIE (i.e. MIS 4, as indicated from Aurín moraines). We know now that this was not the case and that Pyrenean glacier fluctuations, particularly during MIS 3, underwent variations that could be as numerous as those that have been identified on a global scale. The bias comes from the fact that frontal and lateral moraines located upstream from the Würmian MIE terminal moraines have been used to mark deglacial stadials when, in fact, they were constructed during phases of stagnation or, in some case, of glacier readvance.

A similar problem arose after the Global LGM. Several indications suggest that a major and extremely fast deglaciation of the Pyrenean valleys occurred between the Global LGM glacial advance and the beginning of the LGIT. The more direct evidence has been provided by $^{14}$C ages obtained from the buried Grave peatbog (Fig. 6), where the three concordant ages of ca. 20 ka cal BP have shown that the Têt glacier was confined to the cirques as soon as the end of the Global LGM while, a few thousands of years before, probably ca. 21-22 ka, the terminal position of the Têt glacier was located 16 km upstream from the Grave site, i.e. near the Würmian MIE terminal position (Delmas, 2005; Delmas et al., 2008 Fig. 7). In the Querol valley, cosmogenic ages of 19 to 20 ka obtained on bedrock steps situated 3, 5 and 9 km upstream the Global LGM frontal moraine, respectively, plead for similar conclusions (Pallàs et al., 2010). Elsewhere, the real magnitude of this phase of early post-LGM deglaciation is not directly recordable.

![Figure 6. $^{14}$C and $^{10}$Be ages at La Grave (upper Têt River valley).](image)
4.2.3. New data on Pyrenean glaciation during the LGIT

Cosmogenic data acquired over the past few years have significantly enhanced the body of available data on Pyrenean glaciation during the LGIT. Their number is still limited, but they have helped to locate the ice-margin positions of the Lateglacial glaciers in several valleys more precisely and, on this basis, help to compare them with the positions of the Würmian MIE. Figures 3, 4, 5 and 7 show the drastic reduction of the areas concerned. Cosmogenic exposure ages recently obtained from deposits generated by small glaciers of the easternmost part of the range (Têt, Querol, Malniu, Duran, Llosa, Arànser: Delmas et al., 2008; Pallàs et al., 2010; Palacios et al., 2015a), but also by the Noguera Ribagorzana (Pallàs et al., 2006), Ariège (Delmas et al., 2011) and Gállego glaciers (Palacios et al., 2015b), confirm and reinforce the impression conveyed from previous \(^{14}\)C-based conclusions.

The main advantage of cosmogenic data over other dating methods is that they provide an opportunity for dating all the stadials present in a valley, with a potential for attaining a finer resolution of paleoclimatic fluctuations during the LGIT than previously allowed by radiocarbon. However, the relative imprecision and the very nature of the cosmogenic data (which provide exposure ages) do not always allow moraines ascribable to the Oldest Dryas, the Younger Dryas and the Holocene to be distinguished with statistical confidence. Likewise, a comparison of the ages obtained from different Pyrenean valleys would require an uniformization of existing and future data on the basis of the latest calibration standards (NIST SRM 4325 for \(^{10}\)Be dating, Nishiizumi et al., 2007). Nevertheless, a consistent pattern is beginning to emerge despite the limited number of valleys investigated until now.

In the Noguera Ribagorzana valley (cf. Fig. 5, Pallàs et al., 2006), the most consistent results concern the moraines located on cirque floors in the upper part of Bessiberri valley (2700 m), and around the Pleta Naua (2200 to 2400 m) where 6 cosmogenic ages on boulders yielded weighted average ages of \(10.1 \pm 0.6 \) ka (9.9 \pm 1.0 ka, 10.1 \pm 0.9 ka, 10.1 \pm 1.0 ka) and of \(10.2 \pm 0.7 \) ka (10.0 \pm 1.0 ka, 10.1 \pm 1.4 ka, 10.6 \pm 1.1 ka), respectively. The Mulleres moraine, which records the position of a 3 km long glacier, has provided a weighted average age of \(10.4 \pm 1.0 \) ka, i.e. almost identical to an age obtained on a boulder at \(10.4 \pm 1.2 \) ka and another on a polished bedrock step at \(10.3 \pm 1.8 \) ka. Downstream of these Holocene (or Younger Dryas –because cosmogenic ages are minimum exposure durations) moraines, the results obtained from the Noguera Ribagorzana are less uniform and more difficult to interpret. The Santet moraine, which is located 4 km downstream of the Mulleres moraine, has provided three ages at \(14.4 \pm 1.4 \) ka, \(12.3 \pm 1.5 \) ka, and \(16.1 \pm 2.8 \) ka on three different boulders. Because the error bars nonetheless overlap, the authors argue for a weighted average age of \(13.7 \pm 0.9 \) ka and use this result to date the disconnection between the Bessiberri and the upper Noguera Ribagorzana glaciers (Pallàs et al., 2006). Farther downstream, the anomalously young exposures ages (\(13.2 \pm 3.3 \) ka and \(11.7 \pm 1.5 \) ka) obtained from the Refugi de l’Hospitallet bedrock step are perhaps explained by a patch of till which would have covered the sampled rock surfaces for some period of time after the deglaciation of the bedrock step. Till patches on bedrock steps, however, are intrinsically labile, and post-glacial erosion
is likely to clear these materials quite soon after deglaciation. Due to this uncertainty, it is thus equally conceivable that the Refugi de l’Hospitalet bedrock step was covered during the Older Dryas by a glacier whose terminal position cannot be precisely located. Finally, the age of the Bessiberri moraine is more difficult to establish because only two ages have been obtained from polished bedrock steps. One is located downstream (16.3 ± 2.1 ka), and the other upstream (11.7 ± 1.5 ka). These ages are consistent with one another but do not indicate whether the Bessiberri glacial advance occurred during the Oldest Dryas or during the Younger Dryas.

As in the Noguera Ribagorçana, cosmogenic exposure ages in the Têt valley—whether obtained on moraines or on polished bedrock steps—are never perfectly uniform and it is often difficult to decide between the lower age bracket, which would indicate Younger Dryas, and the higher bracket, which indicate Oldest Dryas ages (Fig. 7). Because cosmogenic exposure ages are minimum ages, the second option (Oldest Dryas) was favored for all the moraines dated in the upper part of the Grave valley and the Carlit plateau (Delmas et al., 2008). Here, the key question is rather: what was the extent of the glacial advance that occurred during the Oldest Dryas, knowing that around 19-20 ka cal. BP, i.e. during GS-2b, the terminal positions of the glaciers in this massif were confined to the floors of the cirques? The question arises especially for the upper part of the Têt valley, where the buried peatbog of La Grave offers a reference site that puts into perspective the cosmogenic data acquired locally with the help of other dating methods. Delmas et al. (2008) considered that the Oldest Dryas glacier could not have covered the radiocarbon-dated peatbog because (in contrast, for example, with the Portalet peatbog setting in Spain: Gonzalès-Sampériz et al., 2006), the exposed stratigraphy of the fill sequence shows no sedimentological or mechanical evidence of overriding by ice (e.g. absence of till between the dated peat and the overlying lacustrine and fluvioglacial units, no obvious compaction of the peat, no erosional stratigraphic unconformity). On the basis of this field evidence, the terminal position of the Oldest Dryas glacier was located just upstream from the buried peatbog, at a site ~2150 m where a frontal moraine has yielded two cosmogenic ages of 13.3 ± 2.0 ka and 11.9 ± 1.9 ka. Another age at 12.7 ± 1.4 ka, which was obtained on a lateral moraine generated during a glacial stade whose terminal position is situated 3 km downstream from the Grave peatbog site, has been rejected as unreliable; dating at 13.5 ± 2.0 ka obtained on a polished bedrock step situated 5 km downstream from La Grave site was also deemed unreliable for the same reasons.

Another way of interpreting this dataset is to retain all the cosmogenic results irrespective of up- or down-valley inconsistencies and consider that the Oldest Dryas cooling event in the Têt valley generated a glacial readvance of sufficient magnitude to produce a valley glacier 5 to 8 km long. Moreover, several ages on polished bedrock steps located on the floors of glacial cirques indicate that the last cirque glaciers disappeared in this massif during the Bølling-Allerød interstadial. Finally, the Younger Dryas cooling event seems to have promoted the development of rock glaciers. A similar chronosequence of landforms has been reported for all the smaller glaciated catchments located further west. For the smallest among these (Malniu, Duran, Llosa, Arànser), the last glacial advance occurred during the Oldest Dryas and the definitive disappearance
The last maximum ice extent and subsequent deglaciation of the Pyrenees of the ice occurred at the time of the Bølling-Allerød interstadial (Pallas et al., 2010; Palacios et al., 2015a). In the Querol valley, a cosmogenic age of 16.2 ± 1.8 ka from the Porté bedrock step, and of 14.9 ± 1.3 ka from the Vinyole moraine, has indicated that the Oldest Dryas glacier was about 7 km long in the Orri valley. In this same area, an age of 11.8 ± 0.6 ka obtained for a moraine located on the cirque floor indicates the persistence of a cirque glacier in this part of the massif until the Younger Dryas (Pallàs et al., 2010).

Figure 7. Glacial deposits and their associated ages on the south-easternmost side of the Pyrenees. After Delmas et al. (2008) and Palacios et al. (2015a).

In the Ariège glacial catchment, data on glacial fluctuations during the LGIT are currently limited to two sites (Fig. 3). In the main axis of the Ariège valley, the Petches moraines help to place the lateral ice margin of a 20 km-long trunk glacier resulting from the confluence of three tributary glaciers in the catchment (En Beys, Nabra, and Mourguillou). All these glaciers originate from the north side of the Carlit massif and the easternmost margin of the Aston massif, which are the most elevated and most exposed to moist Atlantic air masses from the northwest. The Petches moraines are positioned 25 km up-valley from the Global LGM moraines, which occur in the Tarascon basin. Cosmogenic exposure ages currently available for the Petches stadial were not obtained from boulders located on the Petches moraine, but instead from three polished bedrock steps situated at Ax-les-Thermes, which lay beneath the Petches glacier at the time. The ages (13.9 ± 2.1 ka, 15.2 ± 3.3 ka and 14.0 ± 0.8 ka) indicate when the Ariège glacier left the Ax-les-Thermes bedrock step and retreated to the higher parts of the valley. Based on these results, (i) the glacial advance responsible for the Petches moraines has been ascribed to the Oldest Dryas, and (ii) the recession of the ice to the upper part of the valley to the Bølling-Allerød interstade.
A second site documents the LGIT glacial extent in the Ariège catchment. This site is located in the Suc valley, a tributary of the Vicdessos River descending from the south side of the Trois Seigneurs massif (2199 m). This site was selected in order to confront cosmogenic ages acquired from this site with existing 14C ages, alongside mineralogical, sedimentological and stratigraphic analysis obtained from a core in the glaciolacustrine fill sequence of Freychinède (Jalut et al., 1982, cf. section 2.1 and Fig. 3). Three cosmogenic ages (16.7 ± 2.3 ka, 14.4 ± 1.1 ka, and 14.1 ± 0.7 ka) were obtained from a polished bedrock step located at 1360-1380 m between the Suc glacial trough and the Freychinède basin. The age sequence indicates that (i) a 150 m-thick glacier occupied the Suc valley during the Oldest Dryas. The terminal position of the small glacier is not easy to locate because there is no frontal or lateral moraine preserved in the Suc valley. However, the thickness of the ice just in front of the dated bedrock step suggests that the terminal position of this Oldest Dryas glacier was about 950 m. (ii) During the Bølling-Allerød interstadial, this glacier gradually retreated until it became confined to the cirques located on the south side of the Trois Seigneurs massif, and soon disappeared definitively. Indeed, it is highly probable that the Younger Dryas cooling event did not promote a new glacial advance in this area. The analysis of leaf stomata from botanical remains collected in the Freychinède borehole allow the Younger Dryas treeline altitude to be estimated at about 1300 m (Reille and Andrieu, 1993), i.e. only 400 to 600 m below the altitude of the cirque floor on the south side of the Trois Seigneurs massif (2199 m). On that basis, and by reference to the current situation, the minimum estimation for the Younger Dryas ELA is about 2300-2500 m, i.e. clearly above the crest of the Trois Seigneurs massif.

Finally, a series of 26 in situ-produced cosmogenic 36Cl ages was recently produced from quartz samples in the upper part of the Gállego catchment (Palacios et al., 2015b, Fig. 4). As in the other Pyrenean valleys, these data were collected from polished surfaces on bedrock steps and from boulders on moraines. The results have allowed the extent of the Oldest Dryas glacial advance to be outlined, and also the rate at which the glacier retreated during the Bølling-Allerød to be characterized. The Oldest Dryas ice extent can be positioned in the Caldarés valley by the Bolática moraine and, in the Aguas Limpias valley, by the Formigal moraine. The location of these two lateral moraines on the valleyside shows that the glaciers in these two valleys were not joined up at that time. They also show that the upper part of the Gállego valley, which is located just below the Portalet pass and does not reach 2300 m, was already ice-free. No cosmogenic exposure ages have been obtained from the Formigal moraine due to a lack of exposed boulders. However, three ages (14.6 ± 2.3 ka, 12.3 ± 1.6 ka, and 11.7 ± 1.7 ka) were acquired in the upper part of the Aguas Limpias valley 8.6 km, 2.6 km and 2.4 km from the cirque headwalls. The Bolática moraine yielded two ages at 16.5 ± 1.8 ka and 13.9 ± 2.0 ka. Behind this moraine, three ages (12.2 ± 1.5 ka, 12.8 ± 1.4 ka, and 13.9 ± 1.8 ka), respectively located 7.3 km, 6 km and 3.075 km from the cirque headwalls, show that the rate of deglaciation in this valley was similar to that in the Aguas Limpias valley. Moreover, these ages on polished bedrock steps indicate the possible presence of residual glaciers on the cirque floors during the Younger Dryas. The ages acquired in the Piniecho and Catieras cirques support this interpretation.
5. Conclusions

The extent and chronology of the Pyrenean glaciation have been the subject of a great number of studies since the 19th century, but the timing of the last deglaciation has only begun to be constrained using radiometric dating since the last 30 years. The position and age of the Würmian MIE have now been well established. The last Pyrenean MIE occurred during MIS 4, and the terminal position of the Würmian MIE glaciers remains poorly defined in areas where deposits have not been well preserved. By contrast, knowledge of glacial fluctuations that occurred after MIS 4 is still in its infancy. Existing data have nonetheless captured the behavior of the Pyrenean glaciers during MIS 3. The fluctuations of outlet-glacier ice margins are relatively well constrained, but the true extent of these changes has not yet been calibrated. We are beginning to discern an east-west gradient in Pyrenean ice extent during the Global LGM, but this remains to be confirmed because of significant knowledge gaps that still remain regarding ice boundaries in some valleys. Evidence about post-LGM deglaciation is also incomplete. Early, rapid and extensive deglaciation can be inferred and extrapolated from local studies, but it is not possible to know yet whether the event occurred throughout the Pyrenees, or whether it only occurred in the massifs under stronger Mediterranean climatic regimes in the east and south. Similar uncertainty concerns the response of Pyrenean glaciers to the sequence of abrupt global climatic changes during the LGIT. Studies currently available are still too scarce to allow a Pyrenean-scale synthesis. The challenge is not so much of a chronological nature because the main climatic changes that occurred in the Pyrenees are the similar to those recorded on a global scale. The Oldest Dryas drove a glacial advance of much lesser magnitude than either the Global LGM or MIS 4. During the Bølling-Allerød interstadial, the ice margins retreated substantially, and some glaciers even locally disappeared. The Younger Dryas cooling event generated either a readvance of the ice front or the development of rock glaciers. The future challenge will be to date the Pyrenean ice extent during the Oldest Dryas, the Bølling-Allerød, the Younger Dryas and the Holocene more precisely than possible until now. Given the transitional position of the Pyrenees between Atlantic and Mediterranean climatic influences, this mountain range forms an ideal laboratory for studying the variability of local responses to abrupt climatic changes during the LGIT. The spatial variability of the ice extent is an interesting proxy that usefully complements existing models provided by vegetation and other biomarkers. Providing greater resolution to the spatial ice extent during the LGIT is therefore probably one of the more important issues for future research on glaciation in the Pyrenees. The task will probably be laborious given the fragmentation of the trunk glaciers into increasingly smaller units as the icefield contracted. But the potential is there because deposits are well preserved and because we now dispose of dating methods well suited to this kind of research.
